Acknowledgements

I would like to thank James Pustejovsky for his guidance and patience throughout the process of developing this thesis, and Lotus Goldberg for her encouragement and instruction that helped lead to the idea for this thesis and the desire to do it. I would also like to thank Nianwen (Bert) Xue for his perspective on problems in semantic representation which helped to shape the approach to the thesis, and Sophia Malamud for her helpful comments and questions. Finally, I would like to thank my family for their advice, interest, and support, and my friends for their tolerance and occasional pressing me to finish.

ABSTRACT

Formalization of AMR Inference via Hybrid Logic Tableaux

A thesis presented to the Faculty of the
Graduate School of Arts and Sciences of Brandeis University
Waltham, Massachusetts

By Eli Goldner

AMR and its extensions have become popular in semantic representation due to their ease of annotation by non-experts, attention to the predicative core of sentences, and abstraction away from syntactic matter. An area where AMR and its extensions warrant improvement is formalization and suitability for inference, where it is lacking compared to other semantic representations, such as description logics, episodic logic, and discourse representation theory. This thesis presents a formalization of inference over a merging of Donatelli et al.'s (2018) AMR extension for tense and aspect with Pustejovsky et al.'s (2019) AMR extension for quantification and scope. Inference is modeled with a merging of Hansen's (2007) tableau method for first-order hybrid logic with varying domain semantics (*FHL*) and Blackburn and Jørgensen's (2012) tableau method for basic hybrid tense logic (*BHTL*). We motivate the merging of these AMR variants, present their interpretation and inference in the combination of *FHL* and *BHTL*, which we will call first-order hybrid tense logic (*FHTL*), and demonstrate the soundness and completeness of *FHTL*'s general tableau method, and its decidability for finite model checking.

0.1 Introduction

AMR’s reductionistic approach to semantic representation enjoys a duly earned popularity in the increasingly data driven environment of post-2000s NLP and CL. Its ablation of fine-grained semantic and syntactic features makes AMR a highly competitive choice for the development of annotated corpora and as a target representation for semantic parsing. It is exactly the aspects of AMR that are so valued that cause it to fall short in an area where historically semantic representations have felt more obligation to succeed, namely interpretation and inference. That AMR has made this compromise is no oversight, but an informed design choice. Version 1.2 of the AMR specification states that by default an AMR does not indicate how it should be processed (Banarescu et al., 2012). Indeed, besides concepts that can be interpreted as propositional connectives like :and, :or, and :cond, there is little that can be directly inferred from a basic AMR besides possibly lexical inference on the concepts and relations. Performing lexical inference directly would require at least extensive hand authoring of relationships between PropBank frames, and in general is beyond the scope of this paper.

AMR extensions ameliorate core AMR’s lack of expressivity by integrating more semantic information into an AMR while still retaining its minimal and predicative structure. Pustejovsky et al. (2019) makes direct inference on AMR significantly easier by providing an unambiguous way to interpret an AMR that makes use of quantification, negation, or modality, while retaining the predicative core of AMR. Donatelli et al. (2018) extends AMR with a treatment of tense and aspect which allows for direct inference involving temporal information. We will show that integrating these two AMR extensions allows for interpretation into a highly expressive logic we call first-order hybrid tense logic *FHTL*, which merges hybrid logic equipped with first order features like (actualist) quantification (Hansen, 2007), and hybrid logic equipped for reasoning about time and tense (Blackburn and Jørgensen, 2012). We present a sound and complete tableau-based proof procedure for *FTHL* sentences. The tableau method is a well known approach to theorem proving that has been adapted to many logics. It works by extracting a tree from a sentence in a logic,

where the nodes consist of root subformulae or supporting formulae to be proved or refuted. We also provide a modified version of this tableau method, which we use to check the satisfiability of translated extended AMR sentences in a finite model, and a method for translating an extended AMR into a *FHTL* formula.

0.2 Motivation

Finding ways to support inference for AMR is no trivial curiosity. For robust and effective natural language understanding, it is arguable that a semantic representation needs to deeply reflect natural language at the expressive level while supporting complex reasoning and capturing both world and domain-specific knowledge (Schubert, 2015). While statistically driven methods add a great deal of value to tasks in deep understanding such as dialogue, question answering, natural language inference, and textual entailment, semantic tasks relevant to these such as disambiguation of discourse sentences (Gardent and Webber, 2001) and pronoun binding (Monz and de Rijke, 1998) are more readily modeled and resolved through automated reasoning and deduction than statistically driven techniques.

Formal methods have historically been the standard means of approaching issues of natural language understanding, and were supplanted by statistically driven methods due in large part to issues of computational expense which have since been greatly mitigated (Schubert, 2015; Gardent and Webber, 2001). Now that statistically driven methods which require significant computing resources and data collection and annotation comprise many of the standard approaches to modern NLP problems, there are questions of how to approach these problems when such resources are not available. Formal methods generally consume less computing space and time than neural networks, and provide a approach to NLP problems for languages where there is insufficient annotated data for other methods. Additionally formal methods are inherently explainable, providing justification for their results, and provide a more ready means of generalizing their approach since their approach depends on the developer, as opposed to statistically driven methods, which in a core sense are limited by the training data they are given and require more advanced methods to track

how they obtain their results (Basu et al., 2020).

As a result, use of formal methods in software is critical if one needs to guarantee or discover properties of software systems. One relevant application is discovery and resolution of bias in NLP systems (Gordon and Durme, 2013), and in general, anywhere software systems have access to sensitive resource one will need to know and ensure certain things about their behavior before deployment. As potentially sensitive software systems increasingly involve natural language interface and rely on natural language data (NLP and dialogue systems for health and mission critical tasks), finding ways to integrate explainability and certainty with natural language tasks will become increasingly relevant. We hope this thesis will be a contribution to this direction of computational linguistics.

0.3 Related Work

0.3.1 Semantic Features in AMR and Possibility of Inference

In recent years there have been more efforts towards extension and interpretation of AMR in ways more suitable to direct inference. Bos (2016) provides a means of translating standard AMR to first-order predicate logic with negation, and that an AMR without recurrent variables under this translation is in the decidable two-variable fragment of first-order predicate logic. (Donatelli et al., 2018) extends sentential AMR to incorporate a coarse grained treatment of tense and aspect, both of which affords inference, and in a very rich way in the case of aspect, as we will discuss at the end. O’Gorman et al. (2018) describes a multi-sentential treatment of AMR with a corpora of examples, for document level semantics in addition to AMR’s current sentential semantics. This has possible implications for document-level and discourse-level inference in AMR, à la discourse representation theory. Pustejovsky et al.’s (2019) extension of AMR with quantification, scope, negation, and modality, is effectively a royal road to interpretation of AMR into first-order logic or related variants, and we will make frequent use of it in section 0.6. (Lai et al., 2020) provides a continuation-based semantics for translating AMR into first-order predicate logic in a way that preserves projective phenomena. While this influenced our interpretation approach, its translation

method is much more elegant than ours, and is closer to the original logical semantics of AMR (Banarescu et al., 2012), we elected not to use it since it uses a Neo-Davidsonian representation for the target first-order predicate logic semantics. This representation is more expensive to handle via tableau-based reasoning, since it guarantees that there is at least one quantifier in the interpretation for every concept in the AMR. Finally, Bonial et al. (2020) provides an AMR extension designed for facilitating natural language understanding in dialogue systems integrating both tense and aspect and a speech act inventory, which conveys the illocutionary force of an utterance accompanying the content. This is another extension that affords the possibility of discourse level inference in addition to sentential inference, which while offering rich conclusions will require a more sophisticated semantics sensitive to context.

0.3.2 Hybrid Logic and Its Extensions

Hybrid logic is an extension of the propositional modal logic allowing for explicit reference to modal states/worlds through a prefix notation. Where ordinary modal logic writes $\Diamond p$ to indicate that there is some world where p holds at some world accessible from that world, hybrid logic by default writes one of $a\Diamond p$, $a:\Diamond p$, or $@_a\Diamond p$ (we use the latter notation from here on), to indicate p holds at some world accessible from a specifically. a in this notation is a *nominal*, which picks out exactly one world in the underlying model. We also say a is true at exactly one world or is the *name* of the world (thus the term nominal). Because of this we can also use the satisfaction operator to denote that two nominals i and j name the same world and consequently share the same content via:

$$@_i j$$

A *world* or *state* in a modal or hybrid model for us is essentially a maximal set of sentences in the language, in particular, for any proposition p and nominal a we have either $@_a p$ or $@_a \neg p$, that is, for any proposition it either holds at the world in question or it does not. Worlds/states can be used to model any notion consistent with them, usually different possible states of affairs, for instance a world identical to ours except New York City is named New Amsterdam, or another

world identical to ours except all cars are green. We can also use worlds/states to model a world or situation at different *times*, for instance everything that exists and is the case right now, exactly thirty five minutes from now, or at 10:23AM UTC May 18th 1997. Where before we mentioned the notion of whether a world or state was *accessible* from the current world, when states are *times*, the question of accessibility is replaced with two questions, namely whether a given time is before or after another (or if they are the same time).

To briefly describe the syntax and semantics of propositional hybrid logic, we have a set of propositional symbols $\text{PROP} = \{p, q, r, \dots\}$, modalities $\text{MOD} = \{m, m', m'', \dots\}$, and *nominals* $\text{NOM} = \{i, j, k, \dots\}$, all nonempty and disjoint from each other. Nominals name states of a model of the logic, usually these states are possible worlds. The basic hybrid language over PROP , MOD , and NOM is given by the grammar:

$$\varphi ::= i \mid p \mid \neg\psi \mid (\psi_1 \wedge \psi_2) \mid (\psi_1 \vee \psi_2) \mid (\psi_1 \rightarrow \psi_2) \mid \langle M \rangle \psi \mid [M] \psi \mid @_i \varphi$$

Where we have only one modality m we write \diamond and \Box for $\langle m \rangle$ and $[m]$. For instance, where the propositional symbol r denotes *Rabia owns a car*, the following are (equivalent) theorems of hybrid logic:

- *It is not possible for Rabia to own a car and for Rabia not to own a car.*

$$\neg\diamond(r \wedge \neg r)$$

- *Necessarily, Rabia owns a car or does not own a car.*

$$\Box(r \vee \neg r)$$

Given our discussion about time, we can use nominals to add the notion of time to these sentences, for instance where i denotes the world at 2015 and j denotes the world at 2021, if we want to indicate that Rabia owned a car in 2015, and that whatever was the case at 2015 is possible in

2021, we can write: $\text{@}_i r \wedge \text{@}_j \diamond i$

First-order Hybrid Logic

First-order modal logic (or quantified modal logic / *QML*) extends first-order predicate logic in a way analogous to how propositional modal logic extends first order propositional logic. An introduction to both QML and propositional modal logic can be found in Fitting and Mendelsohn (1998). As before, a tableau method is a proof procedure for some first-order language (and a decision procedure for a propositional language), and it is the most widely used proof procedure for modal logics (Girle, 2014). In a sense, hybrid logic simply makes explicit through the satisfaction operator what is implicit in modal logic, and indeed, in modal tableau prefixes play an explicit role. As a result the tableau method generalizes to hybrid logics very well. Blackburn and Marx (2002) provides the first tableau method for a first-order extension of hybrid logic. Quantified hybrid logic *QHL* as defined in Blackburn and Marx (2002) unfortunately for us, uses constant-domain semantics and possibilist quantification (where quantifiers range over all the collective domain of all worlds/times), making it inconvenient for modeling quantification and reference in natural language. Furthermore it omits non-unary function symbols, which are a necessity for modeling AMR concepts such as `have-rel-role` in first-order language. Hansen (2007) remedies this by developing a semantics and tableau method for first-order hybrid logic *FHL*, a variant of *QHL* using varying-domain semantics and actualist quantification (quantifiers only range over entities at the time of reference). As can be inferred from the name, *FHL* is the core component of our development of *FHTL* in section 0.4.

Basic Hybrid Tense Logic

The roots of hybrid logic, and hybrid tense logic in particular, range back to the philosopher Arthur N. Prior's work in the 1960s (Prior and Hasle, 2003). We take our treatment of basic hybrid tense logic *BHTL* from Blackburn and Jørgensen (2012), which roughly can be seen as renaming \diamond and \square to *F* and *G* in basic hybrid logic (the modality for the future), and adding their duals under the

accessibility relation P and H (the modality for the past), sometimes written \diamond^{-1} and \square^{-1} . For intuition, if we have $@_i F \varphi$ for some time i , then we have that φ holds at some time in the future from the perspective of i . If we have $@_i G \varphi$, then φ holds at every world in the future from the perspective of i . Similarly for $@_i P \varphi$ and $@_i H \varphi$, except both statements refer to the past from the perspective of i . Now that the accessibility relation R of an interpretation of *BHTL* notionally models time, there are additional properties of R to consider (such as it being a strict partial order) when proving soundness and completeness for the language. This is accomplished in Blackburn and Jørgensen (2012), but in this paper we avoid these considerations and make no assumptions about the model's accessibility relation. Basic hybrid tense logic can be used to model tense at the sentential and discourse levels. For the sentential level, where again r denotes *Rabia owns a car*

- *That Rabia owns a car now, implies that Rabia will own a car.*

$$@_n(r \rightarrow F(r))$$

(This is a theorem only if we make certain assumptions about time.)

For the discourse level, consider the sentences *John entered the room. It was dark. He sat down.*

We can represent them as:

$$P(i \wedge \text{john-enter-room}) \wedge P(j \wedge \text{room-is-dark}) \wedge @_i j \wedge P(k \wedge \text{john-sits-down}) \wedge @_k Pi$$

The event of John entering the room is associated with the state i , and the room being dark is associated with the state j . We have $@_i j$ to indicate that they occur at the same time, $@_k Pi$ to indicate that they happened in the past of the state k associated with John sitting down.

0.4 First-order Hybrid Tense Logic

Here we give a modification of Hansen's First-order Hybrid Logic which describes tense instead of possibility while retaining *FHL*'s varying domain semantics and presentist quantification.

0.4.1 Syntax of *FHTL*

The syntax of *FHTL* is identical to *FHL* as given in Hansen (2007), except \diamond and \square are replaced by their operational equivalents F and G , and their dual temporal modalities P and H are added. The *FHTL* language contains the following (countably infinite) sets: a set of first-order variables **FVAR**, a set of constants **CON**, a set of relation symbols **RSYM**, a set of function symbols **FSYM**, a set of nominals **NOM**, a set of state variables **SVAR**.

Definition 0.4.1 (*FHTL*-terms). Terms in *FHTL* are generated by the following grammar:

$$t ::= x \mid c \mid u:t \mid f(t_1, \dots, t_n)$$

Where $x \in \text{FVAR}$, $c \in \text{CON}$, $u \in \text{NOM} \cup \text{SVAR}$, and f is an n -ary function symbol in **FSYM**. Where a term t is prefixed by a nominal or state variable u as in $u:t$, this is used to denote the value that t attains specifically at the time picked out by u , since as we will see in the semantics of *FHTL*, each time will have its own domain of entities not necessarily equal to the domain of any other time, and interpretation of terms is sensitive to the domain of some particular time. This prefixing of terms, as in $u:t$, permits one to specify that a term is to be interpreted in the context of a given time even if everything else in the formula containing it is to be interpreted in the context of a different time.

Definition 0.4.2 (*FHTL*-formulae). *FHTL*-formulae are generated from the atomic formulae according to the following rules:

$$\varphi ::= R(t_1, \dots, t_n) \mid t_1 = t_2 \mid u \mid \neg\psi \mid \psi_1 \vee \psi_2 \mid (\exists x)\psi \mid F\psi \mid P\psi \mid @_n\psi$$

Where $R \in \text{RSYM}$, t_1, \dots, t_n are *FHTL* terms, $u \in \text{NOM} \cup \text{SVAR}$, and $x \in \text{FVAR}$. We omit definitions for \wedge , \rightarrow , H , G , and \forall for the sake of simplicity (and space), since they can be defined in terms of the other rules.

For example, we can represent the following tense and quantification sensitive natural language

sentences as follows:

- *There currently is a person who will be president.*

$$@_{now}(\exists x)(Person(x) \wedge F(President(x)))$$

- *For every person, they have a parent who existed before them.*

$$(\forall x)(Person(x) \rightarrow P((\exists y)Parent(x,y)))$$

0.4.2 Semantics of FHTL

Since we want each time to have its own domain of entities which exist at that time, we look to Fitting and Mendelsohn's (1998) treatment of first-order modal logic with varying domain semantics and use it to alter the *FHL* model definition to the following:

$$(T, \mathcal{R}, (D_t)_{t \in T}, I_{nom}, (I_t)_{t \in T})$$

Thus with varying domain semantics a *FHTL* model is identical to the definition for a *FHL* model in that:

- (T, R) is a modal frame.
- I_{nom} is a function assigning members of T to nominals.

The differences manifest with regard to the model and interpretation. Namely, where $D = \cup_{t \in T} D_t$, (D, I_t) is a first-order model where:

- $I_t(q) \in D$ where q is a unary function symbol¹.
- $I_t(R) \in D^k$ where R is a k -ary relation symbol.

¹We use these for non-rigid designation and constants for rigid designation, e.g. roles versus names.

If we were using constant domain semantics we would require $I_t(c) = I_{t'}(c)$ for any constant c and any times $t, t' \in T$. But we do not require this since the interpretation of the constant need not exist at both times. This permits us to distinguish between the domain of a frame (everything that exists in the “history” of the model) and the domain of a time, in a way that prevents any first-order variable x from failing to refer at a given time, even if it has no interpretation at that time. Intuitively this permits *FHTL* to handle interpretation of entities in natural language utterances, which while reasonable to refer to, do not exist at a current time, e.g. 19th century US presidents and unknown future US presidents.

Free variables are handled similarly as in *FHL*. Where again $D = \cup_{t \in T} D_t$, a *FHTL* assignment is a function:

$$g: \text{SVAR} \cup \text{FVAR} \rightarrow T \cup D$$

State variables are sent to times/worlds and first-order variables are sent to D , the domain of the frame. Thus given a model and a variable assignment g , the interpretation of a term t denoted by \bar{t} is defined by:

- $\bar{x} = g(x)$ for x a variable and any $t \in T$.
- $\bar{c} = I_t(c)$ for c a constant and some $t \in T$.
- $\overline{f(t_1, \dots, t_n)} = I_w(f)(\bar{t}_1, \dots, \bar{t}_n)$ for f an n -ary function symbol, t_1, \dots, t_n terms, and $w \in T$.
- $\overline{i:t} = I_w(i:t) = I_{i_{\text{nom}}(i)}(t)$ for t a term, i a nominal, and $w \in T$.
- $\overline{u:t} = I_w(u:t) = I_{g(u)}(t)$ for t a term, u a state variable, $w \in T$.

Finally we say an assignment g' is an x -variant of g if g' and g agree on all variables except possibly x . In particular, we say g' is an x -variant of g at a time t , if g' and g on all variables except possibly x and $g'(x) \in D_t$. Finally, given a model \mathfrak{M} , a variable assignment g , and a time s , we have the inductive definition of $\mathfrak{M}, s \models_g \varphi$ as:

$\mathfrak{M}, s \models_g R(t_1, \dots, t_n)$	$\iff \langle \bar{t}_1, \dots, \bar{t}_n \rangle \in I_s(R)$
$\mathfrak{M}, s \models_g t_i = t_j$	$\iff \bar{t}_i = \bar{t}_j$
$\mathfrak{M}, s \models_g n$	$\iff I_{\text{nom}}(n) = s$, for n a nominal
$\mathfrak{M}, s \models_g w$	$\iff g(w) = s$, for w a state variable
$\mathfrak{M}, s \models_g \neg\varphi$	$\iff \mathfrak{M}, s \not\models_g \varphi$
$\mathfrak{M}, s \models_g \varphi \vee \psi$	$\iff \mathfrak{M}, s \models_g \varphi \text{ or } \mathfrak{M}, s \models_g \psi$
$\mathfrak{M}, s \models_g (\exists x)\varphi$	$\iff \mathfrak{M}, s \models_{g'} \varphi$ for some x -variant g' of g at s
$\mathfrak{M}, s \models_g F\varphi$	$\iff \mathfrak{M}, t \models_g \varphi$ for some $t \in T$ such that $\mathcal{R}st$
$\mathfrak{M}, s \models_g P\varphi$	$\iff \mathfrak{M}, t \models_g \varphi$ for some $t \in T$ such that $\mathcal{R}ts$
$\mathfrak{M}, s \models_g @_n\varphi$	$\iff \mathfrak{M}, I_{\text{nom}}(n) \models_g \varphi$ for n a nominal
$\mathfrak{M}, s \models_g @_w\varphi$	$\iff \mathfrak{M}, g(w) \models_g \varphi$ for w a state variable

A formula is satisfiable if there is some model where the formula is true, and a formula is valid if it is true in every model. We also note that if ψ is a sentence (a formula with no free variables), then whether $\mathfrak{M}, s \models_g \varphi$ does not depend on the variable assignment g .

0.4.3 The Tableau Calculus

When working with the tableau calculus (figures 1 and 2), following Hansen (2007) we introduce a countably infinite list of parameters **PAR**, where parameters are constants which are used exclusively to instantiate quantifiers and are never quantified over. We write $s:p$ to indicate a parameter is interpreted in the domain of a nominal s , just as we do with terms. As prefixed constants, parameters refer rigidly in their domain. The *extended language* is the language obtained by adding **PAR** to the standard *FHTL* language. In the tableau rules, a term in the extended language is called a closed term if it contains no first-order variables or state variables.

<u>Propositional rules:</u>
$\frac{@_s(\varphi \vee \psi)}{@_s\varphi @_s\psi} (\vee)$ $\frac{@_s\neg(\varphi \vee \psi)}{@_s\neg\varphi} (\neg\vee)$ $\frac{@_s\neg\neg\varphi}{ @_s\varphi} (\neg\neg)$
<u>Modal rules:</u>
$\frac{@_sF\varphi}{ @_sFa} (F)^{ab}$ $\frac{@_sP\varphi}{ @_sPa} (P)^{ab}$
$\frac{@_s\neg P\varphi \quad @_sPt}{ @_t\neg\varphi} (\neg P)$ $\frac{@_s\neg F\varphi \quad @_sFt}{ @_t\neg\varphi} (\neg F)$
<u>Quantifier rules:</u>
$\frac{@_s(\exists x)\varphi}{ @_s\varphi[s:p/x]} (\exists)^c$ $\frac{@_s\neg(\exists x)\varphi}{ @_s\neg\varphi[s:p/x]} (\neg\exists)^d$
<u>@ rules:</u>
$\frac{@_s @_t\varphi}{ @_t\varphi} (@)$ $\frac{@_s\neg @_t\varphi}{ @_t\neg\varphi} (\neg@)$
$\frac{@_st \quad @_s\varphi}{ @_t\varphi} (\textbf{nom})$ $\frac{[i \text{ on the branch}]}{@_i i} (\textbf{nom ref})$
$\frac{@_sPt}{ @_tFs} (P\text{-trans})$ $\frac{@_sFt}{ @_tPs} (F\text{-trans})$
$\frac{@_sPt \quad @_t u}{ @_sPu} (P\text{-bridge})$ $\frac{@_sFt \quad @_t u}{ @_sFu} (F\text{-bridge})$

^aThe nominal a is new to the branch.

^bThe formula φ is not a nominal.

^c $s:p$ is new to the branch.

^d p is any parameter which exists at s .

Figure 1: First table of *FHTL* rules.

Equality rules:

$$\frac{}{\lhd_i j:t = j:t} \text{ (ref)}^a \quad \frac{\lhd_i j:t = k:s \quad \lhd_i \varphi}{\lhd_i \varphi[j:t//k:s]} \text{ (sub)}^b$$

FHTL term rules:

$$\begin{array}{c} \frac{\lhd_i k_1:t = k_2:s}{\lhd_i k_1:t = k_2:s} \text{ (:1)} \quad \frac{\lhd_i j}{\lhd_k i:t = j:t} \text{ (:2)}^a \quad \frac{}{\lhd_i k:j:t = j:t} \text{ (:3)}^a \\ \\ \frac{\lhd_i R(t_1, \dots, t_n)}{\lhd_i R(i:t_1, \dots, i:t_n)} \text{ (:fix 1)} \quad \frac{\lhd_i \neg R(t_1, \dots, t_n)}{\lhd_i \neg R(i:t_1, \dots, i:t_n)} \text{ (:fix 2)} \\ \\ \frac{\lhd_i t = s}{\lhd_i i:t = i:s} \text{ (:fix 3)} \quad \frac{\lhd_i \neg t = s}{\lhd_i \neg i:t = i:s} \text{ (:fix 4)} \\ \\ \frac{}{\lhd_i f(t_1, \dots, t_n) = f(i:t_1, \dots, i:t_n)} \text{ (:func)}^c \end{array}$$

^aWhere t is a closed term.

^b $\varphi[j:t//k:s]$ is φ where some occurrences of $j:t$ have been replaced by $k:s$.

^c f is an n -ary function symbol and t_1, \dots, t_n are closed terms.

Figure 2: Second table of *FHTL* rules.

0.4.4 Soundness and completeness

The proof of soundness for *FHTL* follows from the soundness of *FHL* established in Hansen (2007), with additions for the rules (P) , $(\neg P)$, (P) -bridge, and (P/F) -trans, the soundness of which are straightforward to demonstrate given the soundness of the corresponding rules for *F*. The proof of completeness is essentially the same as the one given in Bolander and Braüner (2006) for Blackburn's tableau system for standard hybrid logic ($\mathcal{HL}(@)$), with accomodations made for the first order aspects of *FHTL* adapted from Hansen (2007). While Bolander and Braüner (2006) proves termination for Blackburn's tableau system, we cannot do that for *FHTL*, since a terminating tableau system would be equivalent to a general decision procedure for first-order predicate logic. We will however introduce restrictions on the quantifier and term rules in sec-

1.	$\text{@}_s(\exists x)[P((\exists y)[f(x,y) = f(y,x)]) \vee \neg(\exists z)[x = z]]$	Premise
2.	$\text{@}_s P((\exists y)[f(s_1,y) = f(y,s_1)]) \vee \neg(\exists z)[s_1 = z]$	(\exists)
3.	$\text{@}_s P((\exists y)[f(s_1,y) = f(y,s_1)])$	$\text{@}_s \neg(\exists z)[s_1 = z]$
4.	$\text{@}_s Pt$	$\text{@}_s \neg[s_1 = s_1]$
5.	$\text{@}_t(\exists y)[f(s_1,y) = f(y,s_1)]$	$\text{@}_s[s_1 = s_1]$
6.	$\text{@}_t[f(s_1,s_2) = f(s_2,s_1)]$	\otimes

Figure 3: Example *FHTL* tableau.

tion 0.5, which will lead to terminating tableau constructions at the cost of general completeness. This is an appropriate compromise since the purpose of our revised tableau system is finite model checking.

Remark 0.4.1. From here on we normalize formulae such that a negation symbol only occurs within the scope of the satisfaction operator, that is we will always write $\text{@}_s \neg \varphi$ and never $\neg \text{@}_s \varphi$ from now on, even though the two are operationally equivalent.

Definition 0.4.3 (Closed and open). If a tableau branch Θ contains both a formula $\text{@}_s \varphi$ and its negation $\text{@}_s \neg \varphi$ we say the branch is *closed*. If every branch of the tableau is closed we say the tableau itself is closed. If a tableau or branch is not closed we say it is *open*.

A closed tableau is a proof of the unsatisfiability of the tableau's root formula, i.e. there is no model and assignment of variables in which it holds. Thus a tableau proof of an *FHTL* sentence φ is a closed tableau with the root $\text{@}_s \neg \varphi$ for some nominal s not occurring in φ . For instance in figure 3 we have that the right branch is closed, and that the left branch is open, since there are no conditions about the function f available. Since this tableau is not closed, the root formula is satisfiable but not valid.

Definition 0.4.4 (Accessibility Formula). A formula occurrence in a tableau is called an accessibility formula if it is of the form $\text{@}_a F b$ or $\text{@}_a P b$ and is the (first) conclusion of an application of the rule (*F*) or (*P*) respectively.

Definition 0.4.5 (Quasi-subformula). A formula φ is a *quasi-subformula* of a formula ψ if one

of the the following is the case:

1. φ is a subformula of ψ modulo substitution of free variables in φ for parameters, and full or partial substitution of a term with an equivalent term.
2. φ is of the form $\neg\chi$ where χ is a subformula of ψ modulo substitution of free variables in χ for parameters, and full or partial substitution of a term with an equivalent term.

Adapting this definition from Bolander and Braüner (2006) to allow parameters being substituted for free variables, and full or partial substitution of any term with an equivalent term, ensures compatibility of the definition with the quantifier rules, term rules, and equality rules. We say a formula $@_s\varphi$ on a *FHTL* tableau branch Θ is a *root subformula* if φ is a quasi subformula of the root formula of the tableau.

Remark 0.4.2. If $@_s\varphi$ occurs on a branch Θ we may write $@_s\varphi \in \Theta$.

Lemma 0.4.1 (Root Subformula Property). *If a formula $@_s\varphi$ occurs in a FHTL tableau where φ is not of the form b , Fb , or Pb for b a nominal, or $u = t$ for optionally prefixed closed terms t and u , then φ is a (positively occurring) root subformula. If $@_s\neg\varphi$ occurs in a FHTL tableau then φ is a root subformula, but we say it is negatively occurring.*

Proof. This is verified by checking the tableau rules with attention to the fact that if the conclusion of a rule is of the form $@_s\neg\psi$ then its premise is of the form $@_s\neg\varphi$, e.g. none of the tableau rules can introduce a leading negation symbol. \square

Definition 0.4.6. An occurrence of a nominal in a formula is *equational* if the occurrence is a formula (i.e. not part of a satisfaction operator).

For instance, the occurrence of a nominal c is equational in the formula $@_a(c \vee (\exists x)\psi)$ but not in the formula $@_c(\exists x)\psi$.

Definition 0.4.7 (N_Θ). The set of nominals which occur on a branch Θ is written N_Θ

Definition 0.4.8 (\sim_Θ). Where Θ is a *FHTL* tableau branch, define a binary relation \sim_Θ on N_Θ by $a \sim_\Theta b$ if and only if $@_a b$ occurs on Θ . Let \sim_Θ^* be reflexive, transitive, and symmetric closure of \sim_Θ .

Theorem 0.4.2. *Where $@_a b$ occurs on a branch Θ , if the nominals a and b are distinct, then each has the property that it is identical to, or related by \sim_Θ to, a nominal with a positive and equational occurrence in the root subformula.*

Proof. This is verified by checking each rule, in some cases making use of 0.4.1. **(nom ref)** might initially appear to be a problem, since we are permitted to apply it for any nominal on the branch, but the nominals in its conclusion are not distinct. For **(F)** and **(P)** we make use of the restriction that they cannot be applied to premises of the form $@_a F\varphi$ or $@_a P\varphi$ where φ is a nominal. \square

Theorem 0.4.3. *Let $@_a Fb$ be a formula occurrence on a branch Θ of a tableau. Either there is a positively occurring subformula Fb' of the root formula such that $b \sim_\Theta^* b'$ or there is an accessibility formula occurrence $@_{a'} Fb'$ such that $a \sim_\Theta^* a'$ and $b \sim_\Theta^* b'$. Similarly for a formula occurrence $@_a Pb$.*

Proof. This is verified by checking each of the tableau rules, in some cases making use of lemma 0.4.1. \square

Definition 0.4.9 (\subseteq_Θ). Where a and b are nominals occurring on an *FHTL* tableau branch Θ , a is *included* in b with respect to Θ if for any root subformula φ , if $@_a \varphi$ occurs on Θ then $@_b \varphi$ also occurs on Θ , similarly for their negations. If a is included in b with respect to Θ , and the first occurrence of b on Θ is before the first occurrence of a on Θ , then we write $a \subseteq_\Theta b$.

Definition 0.4.10 (W, \approx). Let W be the subset of N_Θ containing any nominal a with the property that there is no nominal b such that $a \subseteq_\Theta b$. Let \approx be the restriction of \sim_Θ to W .

We can see that W contains every nominal in the root formula, and since any branch Θ is closed under **(nom ref)** and **(nom)** we have that \sim_Θ and \approx are equivalence relations. For a nominal a in W we write $[a]$ to denote the equivalence class of a under \approx and W/\approx to denote the set of equivalence classes.

Definition 0.4.11. Let R be the binary relation defined on W defined by Rac if and only if there are nominals $a' \approx a$ and $c' \approx c$ satisfying one of the following conditions:

1. The formula $@_{a'}Fc'$ or $@_{a'}Pc'$ occurs at Θ and was introduced to the branch by F or P respectively.
2. There is a nominal $d \in N_\Theta$ such that the formula $@_{a'}Fd$ or $@_{a'}Pd$ was introduced to the branch by F or P respectively and $d \subseteq_\Theta c'$
3. The formula $@_{a'}Fc'$ or $@_{a'}Pc'$ occurs at Θ and a' or c' occurs in the root formula.

Note that the nominal d in the second item is not an element of W and that the accessibility relation R is compatible with \approx . We define \bar{R} as the binary relation on W/\approx defined by $\bar{R}[a][c]$ if and only if Rac . (W, \bar{R}) is a modal frame, the first step towards constructing a model of an open tableau branch Θ .

0.4.5 First-Order Components for Completeness

Completeness for a tableau system is demonstrated by giving a method for constructing a model from an open branch such that it satisfies every formula on the branch. Taking our cue from Hansen (2007) and making accomodations for the tableau rules and structure we adapted from Bolander and Braüner (2006), we construct the first-order components of our model. Here we define the analogues of $D_{[w]}$, $I_{[w]}$ for $[w] \in W/\approx$ and I_{nom} . To start we let \mathcal{D} be set defined by:

$$\mathcal{D} = \{i:t \mid \text{for } i \in W \text{ and } t \text{ a closed term of the extended language}\}$$

Further we define a relation \equiv on D by: $i:t \equiv j:s \iff @_k i:t = j:s \in \Theta$ for some $k \in W$. From the tableau rules **(ref)**, **(sub)**, and **(:1)**, we observe \equiv is an equivalence relation on \mathcal{D} . From here we define the domain D of the new model's frame as \mathcal{D}/\equiv , with the elements written as $\overline{i:t}$. For every $[w] \in W/\approx$ define:

$$D_{[w]} = \{\overline{j:p} \mid j \in [w] \text{ and } p \text{ a parameter}\}$$

For c a constant or parameter and $[w] \in W/\approx$ we define $I_{[w]}(c) = \overline{w:c}$ which is well defined by (2).

For an n -ary relation symbol R and $[w] \in W/\approx$ define $I_{[w]}(R)$ by:

$$I_{[w]}(R)(\overline{i_1:t_1}, \dots, \overline{i_n:t_n}) \iff @_w R(i_1:t_1, \dots, i_n:t_n) \in \Theta$$

for all $\overline{i_1:t_1}, \dots, \overline{i_n:t_n} \in D$. The interpretation is similar for n -ary function symbols. And naturally for interpretation of nominals, for $w \in W$ define $I_{nom}(w) = [w]$. Before finally demonstrating that this model \mathfrak{M} realizes every formula on the tableau branch from which it was constructed we need the following lemma.

Lemma 0.4.4. *If t is a closed term of the extended language and i is a nominal, we have $I_{[i]}(t) = \overline{i:t}$ for every variable assignment g in our model \mathfrak{M} .*

Proof. The proof is by induction on the construction of t . By our assumption t cannot be a first-order variable, and if t is a constant or a parameter then

$$I_{[i]}(t) = \overline{i:t}$$

by definition. Suppose alternatively t is of the form $u:s$ for $u \in W$, since t contains no variables neither does s and consequently:

$$I_{[i]}(u:s) = I_{[u]}(s) \stackrel{*}{=} \overline{u:s} \stackrel{(3)}{=} \overline{i:u:s}$$

Where $*$ follows from the inductive hypothesis and (3) from (3). Similarly for the case of terms beginning with function symbols. \square

Theorem 0.4.5 (Completeness of the FHTL Tableau Method). *Assuming the branch Θ is open, for any formula $@_a \varphi$ which contains only nominals from W , the following two statements hold:*

$\text{@}_a \varphi \in \Theta \implies \mathfrak{M}, [a] \models_g \varphi$ for some (all) variable assignments g

$\text{@}_a \neg \varphi \in \Theta \implies \mathfrak{M}, [a] \not\models_g \varphi$ for some (all) variable assignments g

Proof. This is demonstrated by induction on the structure of φ . We present the most difficult case, namely where φ is of the form $F\psi$, lemma 0.4.4 is used in the cases of formulae which directly depend on terms.

Assume $\text{@}_a F\psi \in \Theta$. Then we need to show that there is an equivalence class $[c] \in W/\approx$ such that $\bar{R}[a][c]$ and $\mathfrak{M}, [c] \models_g \psi$ for some variable assignments g . We have two cases based on the question of whether or not ψ is a nominal. In the case where

- ψ a nominal Suppose ψ is some nominal b , we only need to prove $\bar{R}[a][b]$. By theorem 0.4.3 there is either a root nominal b' such that $b' \sim_\Theta b$ or there is an accessibility formula $\text{@}_{a'} Fb' \in \Theta$ such that $a' \sim_\Theta a$ and $b' \sim_\Theta b$. In the first case then we have $\text{@}_a Fb' \in \Theta$ and $b' \in W$ so $\bar{R}[a][b']$ and since $b' \approx b$ (since both are in W) we have $[b'] = [b]$ and we are done. In the second case, there are four subcases depending on whether or not a' and a are equal and b' and b are equal:

- $a' = a$ and $b' = b$:

Then we have $\bar{R}[a][b]$ and are done.

- $a' = a$ and $b' \neq b$:

By theorem 0.4.2 there is a nominal c occurring in the root formula such that $b' \sim_\Theta c$.

But then $\text{@}_a Fc \in \Theta$ and $c \in W$ so $\bar{R}[a][c]$, and by the definition of \approx we have $[c] = [b]$ and are done.

- $a' \neq a$ and $b' = b$:

By theorem 0.4.2 there is a nominal c occurring in the root formula such that $a' \sim_{\Theta} c$.

But then $@_c F b \in \Theta$ and $c \in W$ so $\bar{R}[c][b]$, and by the definition of \approx we have $[c] = [a]$ and are done.

- $a' \neq a$ and $b' \neq b$:

By theorem 0.4.2 there are nominals c and d occurring in the root formula such that $a' \sim_{\Theta} c$ and $b' \sim_{\Theta} d$. But then also $@_c F d \in \Theta$, and $c, d \in W$ so $\bar{R}[c][d]$ and by definition of \approx we have $[c] = [a]$ and $[d] = [b]$ and are done.

- ψ not a nominal Since $a \in W$ the application of (F) to $@_a \psi$ is not blocked by the loop-check condition of the tableau construction algorithm. From the rule (F) , there are formulae $@_a F c, @_c \psi \in \Theta$ where the nominal c is new to the branch. If $c \in W$ then $\bar{R}[a][c]$ and by induction $\mathfrak{M}, [c] \vDash_g \psi$ for every variable assignment g . If $c \notin W$ then by the definition of W there is a nominal d where $c \subseteq_{\Theta} d$. Without loss of generality assume there is no nominal e such that $d \subseteq_{\Theta} e$, this implies $d \in W$. Additionally by lemma 0.4.1 ψ is a root subformula and we have $@_d \psi \in \Theta$. By induction we have $\mathfrak{M}, [d] \vDash_g \phi$, and by the definition of W and \approx we have $\bar{R}[a][d]$.

Now assume $@_a \neg F \psi \in \Theta$, we need to show $\mathfrak{M}, [a] \not\vDash_g F \psi$ for every variable assignment g , i.e. for any $[c] \in W/\approx$ where $\bar{R}[a][c]$ that $\mathfrak{M}, [c] \not\vDash_g \psi$ for any variable assignment g . From $\bar{R}[a][c]$ we have that there are nominals $a' \approx a$ and $c' \approx c$ satisfying one of the three conditions of R in definition 0.4.11. From the first and third conditions we have $@_{a'} F c' \in \Theta$ and as a result $@_a F c \in \Theta$ and in turn by $(\neg F)$ we have $@_c \neg \psi \in \Theta$. By induction we have $\mathfrak{M}, [c] \not\vDash_g \psi$ for every variable assignment g . In the second condition of R in definition 0.4.11 there is a nominal $d \in N_{\Theta}$ such that $@_{a'} F d \in \Theta$ and $d \subseteq_{\Theta} c'$, consequently $@_a F d \in \Theta$ and by $(\neg F)$ we have $@_d \neg \psi \in \Theta$. But by lemma 0.4.1 ψ is a root subformula, and since $d \subseteq_{\Theta} c'$ we have $@_{c'} \neg \psi \in \Theta$. By induction we have $\mathfrak{M}, [c'] \not\vDash_g \psi$ for every variable assignment g and by the definition of \approx also $[c'] = [c]$. \square

0.5 *FHTL* Model Checking with Finite Tableaux

For our task of AMR inference, we are not always concerned with determining the general satisfiability or validity of an AMR formula translated into *FHTL*, but rather whether it holds in a model consistent with an established set of *FHTL* translations of AMR sentences.

This is because reasoning about AMR sentences (or eventually even about AMR representing discourses or documents) takes place in a particular context or a general kind of context. These contexts are described in logic by models, and where they are determined by some finite set of AMR sentences, these models will necessarily be finite, since across any finite number of AMR sentences only a finite number of times (nominals), entities (terms of the extended language), and relationships between entities (function symbols and relation symbols) can be referenced. It is possible for some contexts to require non-finite models, or for some model conditions to be so general as to require automated theorem proving techniques for assessing a sentence rather than automated model checking, but these issues are beyond the scope of this paper.

For *FHTL* sentences and finite models, we have an instance of a local model-checking problem where given formula φ , a finite *FHTL* model structure \mathfrak{M} , a time t in \mathfrak{M} , and a variable assignment g , we need to determine whether $\mathfrak{M}, t \models_g \varphi$ (Müller-Olm et al., 1999). Here we develop a restriction of our method for tableau construction. Which ensures termination of tableau construction (i.e. all resulting tableaux are finite) at the cost of completeness. This is actually an easy compromise for us to make. Model checking via tableau does not benefit from the completeness of a tableau method, since we are not trying to demonstrate a sentence's validity or unsatisfiability, but only whether it holds in the relevant model. Tableau termination however is critical to decidability, and since we are assuming finite models, our approach had better be decidable! Our approach to using terminating tableaux as a means of model checking for *FHTL* is based on the approach in Bohn et al. (1998), and makes use of the idea of quantifier depth from Fitting (1988). The structure of the proof of terminating construction is taken from Bolander and Braüner (2006).

0.5.1 Restricted rules

Restricted equality rules:

$$\frac{[i \text{ and } j \text{ on the branch.}]}{@_i j:t = j:t} \text{ (ref)}^a$$

$$\frac{@_i j:t = k:s \quad @_i \varphi}{ @_i \varphi[j:t//k:s]} \text{ (sub)}^b$$

Restricted term rules:

$$\frac{@_i j_1:t = j_2:s \quad @_k j_1:t = j_2:s}{ @_k j_1:t = j_2:s} \text{ (:1)}^c \qquad \frac{@_i j}{ @_k i:t = j:t} \text{ (:2)}^{cd} \qquad \frac{@_k j:i:t = i:t}{ @_k j:i:t = i:t} \text{ (:3)}^{cd}$$

$$\frac{@_i R(t_1, \dots, t_n)}{@_i R(i:t_1, \dots, i:t_n)} \text{ (:fix 1)}^e$$

$$\frac{@_i \neg R(t_1, \dots, t_n)}{@_i \neg R(i:t_1, \dots, i:t_n)} \text{ (:fix 2)}^e$$

$$\frac{@_i t = s}{ @_i i:t = i:s} \text{ (:fix 3)}^e$$

$$\frac{@_i \neg t = s}{ @_i \neg i:t = i:s} \text{ (:fix 4)}^e$$

$$\frac{[i \text{ and one of the two function terms on the branch}]}{@_i f(t_1, \dots, t_n) = f(i:t_1, \dots, i:t_n)} \text{ (:func)}^f$$

Restricted universal rule:

$$\frac{@_s \neg (\exists x) \varphi}{ @_s \neg \varphi[s:p/x]} \text{ (\neg\exists)}^g$$

^a t is a closed term on the branch, j not among its prefixes.

^b $\varphi[j:t//k:s]$ is φ where some occurrences of $j:t$ have been replaced by $k:s$.

^c k on the branch.

^d t is a closed term on the branch, and i, j are distinct nominals on the branch, not among the prefixes of t .

^e i is not among the prefixes of the terms in the conclusion.

^f f is an n -ary function symbol and t_1, \dots, t_n are closed terms with i not among their prefixes.

^g p is any parameter on the branch (or any parameter in general if there are none on the branch yet), and the premise can produce only Q distinct conclusions.

Figure 4: Restricted Rules.

Definition 0.5.1 (Saturation). A tableau branch is *saturated* if there are no rules that can be applied to the branch in a way that satisfies their constraints or that would generate duplicate

formulae on the branch. If every branch of the tableau is saturated we say the tableau is saturated.

We will show later that the new restrictions on the equality rules, term rules, and the universal quantifier rule given in figure 4 ensure that eventually any branch will be saturated, since the amount of times any of the term rules can be applied depends on the number of nominals and terms on the branch. In first-order tableau systems universal rules are the main culprit for non-terminating construction. Since proofs are finite objects, any tableau proof for a formula involving universal quantification will close for some quantifier depth Q , the issue being there is no general way to anticipate the value of Q as that would constitute a decision procedure for first-order logic. The main function of a universal rule in a tableau proof is to close the branch, so selecting a particular quantifier depth is a way of giving a branch every reasonable chance to close where it has a possible application of a universal rule. While for model checking we actually will not need branches to close so long as they terminate, closed branches are helpful since we do not have to check them for satisfiability.

0.5.2 Systematic tableau construction

Definition 0.5.2 (\prec_Θ). Where Θ is a tableau branch in the *FHTL* calculus, if a nominal a is introduced to the branch by an application of of (F) or (P) to a premise $@_s\varphi$, we say a is *generated* by s on Θ and write $s \prec_\Theta a$.

Lemma 0.5.1. *Where Θ is a tableau branch in the FHTL calculus, the graph $G = (N_\Theta, \prec_\Theta)$ is the disjoint union of a finite set of well-founded and finitely branching trees.*

Proof. Each aspect is proved below:

- *Wellfoundedness of trees in G*

We have that if $a \prec_\Theta b$ then the first occurrence of a on Θ is before the first occurrence of b , thus by induction any subset of N_Θ under the relation \prec_Θ has a least element and each tree in G is wellfounded.

- *G is a disjoint union of a set of trees*

This follows from well-foundedness, the fact every nominal in N_Θ can be generated by at most one other nominal, and that every nominal in N_Θ must have one of the finitely many nominals in the root formula as an ancestor.

- *The set of trees is finite*

If a nominal c occurs on a branch but not in the root formula then there is some nominal a which generated c , as a result c cannot be the root of a tree, and since there are only finitely many nominals in a root formula there can only be finitely many trees.

- *Each tree finitely branching*

We show some tree \mathcal{T} is finitely branching by showing that given a nominal a , there can only be finitely many distinct nominals b such that $a \prec_\Theta b$. Each nominal b such that $a \prec_\Theta b$ is generated by applying one of F, P to a premise of the form $@_a F \varphi$ or $@_a P \varphi$ respectively, where by our restrictions φ is not a nominal. Since there can only be finitely many root subformulae of the form of one of the possible premises, where a is the prefix nominal in each case, only finitely many new nominals have been generated from a . Thus \mathcal{T} is finitely branching.

□

Remark 0.5.1. In the restricted rules, a term can have no nominal among its prefixes more than once. In particular, where n is the number of nominals on the branch and $k(\leq n)$ is the length of a term's prefix string, the number of possible prefixed versions of a term are

$$\sum_{k=1}^n \frac{n!}{(n-k)!}$$

Lemma 0.5.2. *Using the restricted rules, minus any rules which generate new nominals on a branch (F and P), any FHTL tableau branch Θ saturates within a finite number of rule applications.*

Proof. The propositional rules, $(\neg F/P)$, (\exists) and the @ rules, have only finitely many possible applications before they can no longer be applied on Θ . With the quantifier depth restriction $(\neg \exists)$ can only be applied a finite number of times, and **(sub)** can generate only finitely many conclusions since there are only finitely many partial substitutions possible for any formula. For **(ref)** and the term rules, we have at worst cases like **(:3)** and **(ref)** which depend on both the number of nominals and the number of terms on the branch for the number of possible applications before saturation. There are only finitely many nominals and terms on the branch at any given time, and by our remark, there are finitely many possible prefix strings for a given term. Thus there are only finitely many possible applications of **(ref)** to the branch. \square

Definition 0.5.3 (*Tableau construction algorithm*). Let $@_a\varphi$ be the formula whose local satisfiability (possibly validity) we are deciding. We inductively define a sequence of finite tableaux

$$\mathcal{T}_0, \mathcal{T}_1, \mathcal{T}_2, \dots$$

where each element of the sequence is embedded in all of its successors. We let \mathcal{T}_0 be the finite tableau consisting of the formula $@_a\neg\varphi$. Assuming the finite tableau \mathcal{T}_n is defined, apply where possible, an arbitrary model checking tableau rule with the following restrictions.

- **Saturation**

Do not apply a rule to a premise if all possible conclusions already occur on the branch.

- **(Loop check)**

The rule **(F)** is not applied to a formula occurrence $@_a F \varphi$ at a branch Θ if there is a nominal b such that $a \subseteq_\Theta b$, and similarly for the rule **(P)**.

Let \mathcal{T}_{n+1} be the resulting tableau.

The saturation conditions prevent the algorithm from extending the tableau indefinitely with redundant formulae and forces the algorithm to use every applicable rule the maximum possible

amount of times, i.e. this algorithm is “fair”, every possible approach to a proof will be explored (Fitting and Mendelsohn, 1998). The loop check condition is designed in the same spirit, preventing the algorithm from introducing nominals to the branch which would be redundant in their sharing identical information with some ancestor nominal already on the branch. Now we demonstrate the algorithm always terminates.

Theorem 0.5.3. *The systematic tableau construction algorithm terminates.*

Proof. Suppose by contradiction the algorithm does not terminate. Then the tableau is an infinite branch Θ . By lemma 0.5.1 the graph (N_Θ, \prec_Θ) is a disjoint union of a finite set of finitely branching trees. Since Θ is infinite the graph has some infinite branch

$$a_1 \prec_\Theta a_2 \prec_\Theta \dots \prec_\Theta a_i \prec_\Theta \dots$$

otherwise by lemmata 0.4.1 and 0.5.2 there would only be finitely many formulae on the branch, contradicting that it is infinite. For each i in the indices of this infinite chain of nominals, let Θ_i denote the initial segment of Θ up to but not including the first formula where the nominal a_{i+1} occurs. Thus one of (F) or (P) was applied to a formula in Θ_i which generated a_{i+1} . Let Γ_i be the set of all formulae which contain any root subformulae φ such that $@_{a_i}\varphi \in \Theta_i$ and let Δ_i be the set of all formulae which contain any root subformulae φ such that $@_{a_i}\neg\varphi \in \Theta_i$. Since there can only be finitely many sets of root subformulae, there are nominals in the infinite chain a_j, a_k where $j < k$ and $\Gamma_j = \Gamma_k$ and $\Delta_j = \Delta_k$. Since $j < k$ the first occurrence of a_j on Θ_k must be before the first occurrence of a_k on Θ_k . Additionally for any root subformula φ , if $@_{a_k}\varphi \in \Theta_k$ then $\varphi \in \Gamma_k$ and consequently $\varphi \in \Gamma_j$, but then $@_{a_j}\varphi \in \Theta_j$ which is an initial segment of Θ_k . Thus by definition 0.4.9 a_k is included in a_j with respect to Θ_k , and since the first occurrence of a_j is before the first occurrence of a_k we have $a_k \subseteq_\Theta a_j$. But this contradicts that (F) or (P) was applied on Θ_k resulting in the first formula containing an occurrence of the nominal a_{k+1} since $a_k \subseteq_\Theta a_j$ would result in the loop check condition blocking the application. Thus the algorithm terminates.

□

0.5.3 Node Annotation

The approach to model checking via tableau involves annotating each node of an open branch with the variable assignments in the model which satisfy the sentence at the node, building inductively from the terminal nodes. If the root formula of the tableau with at least one open branch can be annotated with a non-empty set of variable assignments, then it is satisfiable in the model, however if the root formula is a sentence, then for it to be satisfied we require that it can be annotated with the set of all variable assignments for the model. If a tableau is closed then the root sentence $\text{@}_s\varphi$ is unsatisfiable. As a result if the root formula is of the form $\text{@}_s\neg\psi$ then this constitutes a proof of the validity of $\text{@}_s\psi$ by contradiction. We now view each node in the tableau graph as a pair $(\text{@}_s\varphi, \mathcal{V})$, of the formula at the node and the set \mathcal{V} of variable assignments in our model \mathfrak{M} which satisfy the formula. We define an annotation function $\text{ann}(\text{@}_s\varphi) = \mathcal{V}$ generally as:

$$\text{ann}(\text{@}_s\varphi) = \{g \mid \mathfrak{M}, I_{\text{nom}}(s) \models_g \varphi\}$$

If we have a branch that we know to be closed from the tableau construction (or discover it is closed during model checking as we will see) and $\text{@}_t\psi$ is the root of that branch, we define:

$$\text{ann}(\text{@}_t\psi) = \emptyset$$

During the annotation process we need not check formulae of the form $\text{@}_i j$ or $\text{@}_i(F/P)j$ since their truth or falsehood is independent of variable assignments. Terminal nodes will necessarily not contain quantifiers, double negation, nested satisfaction operators, or logical connectives, as a result they will consist only of equality and/or relation statements over extended terms possibly involving free variables. Now we can begin describing the dependency relationships between tableau rule conclusions and their premises.

- **Term rules:** In all cases we can see that for every rule with a premise the same variable assignments which satisfy the conclusion satisfy the premise. This is immediate for (2), (3),

and (**:func**), since they only involve closed terms, and are verified by checking definitions in all other cases.

- **@ rules:** For (***P/F*-bridge**), and (***P/F*-trans**) all variable assignments trivially satisfy both the conclusions and premises. For (**nom**), since by the first premise

$$I_{\text{nom}}(i) = I_{\text{nom}}(j)$$

the variable assignments that satisfy the conclusion satisfy the second premise (the first premise being a nominal equivalence is trivially satisfied by all variable assignments). That the premise and conclusion of both (@) and (\neg @) are satisfied by the same variable assignments are verified by checking their satisfiability definitions.

- **Equality rules:** The only rule to check is (**sub**), from which it follows immediately that the second premise is satisfied by the variable assignments which satisfy both the conclusion and the constraint given by the first premise, namely that $\overline{j:t} = \overline{k:s}$, which both involve free variables. If both of $\overline{j:t}$ and $\overline{k:s}$ are closed terms then there is no constraint on the variable assignments to consider.
- **Quantifier rules:** For (\exists), we let C be set of variable assignments which satisfy the conclusion. Without loss of generality, where the premise is $@_s(\exists x)\varphi$, we see from the semantics of \exists that P , the set of variable assignments which satisfies the premise can be defined as:

$$P = \{g \mid g \in C \text{ such that there is an } x\text{-variant } g' \text{ of } g \text{ at } s \text{ where } \mathfrak{M}, s \models_{g'} \varphi\}$$

Similarly for ($\neg\exists$) let C be the set of variable assignments which satisfy the conclusion. Without loss of generality, where the premise is $@_s\neg(\exists x)\varphi$, we see from the semantics of $\neg\exists$ that P , the set of variable assignments which satisfies the premise can be defined as:

$$P = \{g \mid g \in C \text{ such that for every } x\text{-variant } g' \text{ of } g \text{ at } s \text{ we have } \mathfrak{M}, s \models_{g'} \neg\varphi\}$$

- **Modal rules:** For (F) and (P) , that the premise and the second conclusion are satisfied by the same variable assignments follows from checking the definitions. Similarly for the first premise and the conclusion of $(\neg P)$ and $(\neg F)$.
- **Propositional rules:** For (\vee) given the semantics of the premise, the union of the sets of variable assignments satisfying each of the conclusions satisfies the premise. Similarly for $(\neg \vee)$, except we take the intersection of the variable assignment sets. That the premise and conclusion of $(\neg \neg)$ are satisfied by the same set of variable assignments follows from checking the semantics.

Remark 0.5.2. We note that any annotation of variable assignments for a node will be finite since any formula will have only finitely many variables, and the model's domain itself is finite.

Lemma 0.5.4. *Node annotation for a model checking tableau over a finite model is decidable.*

Proof. We give an inductive argument, where the base cases are equality or relation statements (or negations thereof) over closed terms of the extended language. First we consider closed terms. Since any model checking tableau is finite, it has only finitely many function symbols, constants, and parameters. Since parameters are not free variables but stand in for them, we will handle them as follows: Recalling every parameter is of the form $j:\dots:i:p$ with a string of at least one distinct prefix, (i is called the *immediate prefix* in the example) we have the following process. Without loss of generality, let i be the immediate prefix for the parameter in question below:

1. Proceeding with annotation as normal, ignore any parameter until reaching the lowest equality or relation statement where it appears in the conclusion, then solve for the values in $D_{I_{nom}(i)}$ for which the parameters would satisfy the formula. Clearly this process terminates since for any nominal i , $D_{I_{nom}(i)}$ is finite.
2. From here on, we compute the sets of parameters which satisfy a formula as we would its set of variable assignments with the exception of quantified formulae which we will cover later. In particular, for a case of (\vee) as in $@_s(\varphi[i:p] \vee \psi[i:p])$ we take the union of the

parameter sets for $@_s \varphi[i:p]$ and $@_s \psi[i:p]$, similarly taking the intersection of the sets of the conclusions in the case of $(\neg\vee)$

The proof of termination for computing these parameter annotations for each node is essentially the same as the proof of termination for variable assignment annotations, so without loss of generality we omit the former and proceed with the latter. The model has only finitely many times and a finite domain for each time, consequently computing the value of a equality or relation statement (or negation thereof) over closed terms is guaranteed to terminate and the annotation consists of every possible variable assignment¹. Since the $\@$ rules, modal rules, and $(\neg\neg)$ do not involve any operations on the set of variable assignments satisfying the conclusions, by induction these node annotations terminate. Assume by induction computing the annotations for the conclusions of (\vee) and $(\neg\vee)$ terminates. Recalling remark 0.5.2, we see that (\vee) and $(\neg\vee)$ involve only union and intersection of finite sets respectively, thus computing them terminates. For **(sub)** we assume by induction that computing the annotations for the first premise and the conclusion terminates, since they are finite, computing their intersection terminates and we have the annotation for the second premise. Finally assume by induction that computing the annotations for the conclusions of (\exists) and $(\neg\exists)$ terminates. For (\exists) , assuming without loss of generality the premise is of the form $@_s(\exists x)\varphi$. Recalling remark 0.5.2 again, we check each variable assignment from a finite set whether it has an x -variant at s that satisfies the premise stripped of its quantifier. But since we have parameter annotations, it suffices to check if the conclusion's parameter annotation is non-empty, since that ensures for any variable assignment an appropriate x -variant could be constructed. As a result if the parameter annotation is non-empty then the variable assignment annotation for the premise is the same as for the conclusion, clearly this step of the process terminates. Similarly for $(\neg\exists)$, in determining whether the variable assignments in the annotation for the conclusion satisfy the premise, it suffices the annotation for the relevant parameter, say $i:p$ is the same size as $D_{I_{nom}(i)}$. If they are the same size then the annotation of variable assignments for the premise is the same as for the conclusion, and since $D_{I_{nom}(i)}$ is finite this terminates. \square

¹Any implementation of this process would represent the totality of variable assignments via a flag which would consume only constant space, similarly for parameter annotations until we solve for them.

Theorem 0.5.5. *Finite model checking for FHTL via restricted tableau is decidable.*

Proof. This follows immediately from theorem 0.5.3 and lemma 0.5.4. \square

0.6 AMR Interpretation in FHTL

In this section we present an approach for translating AMR annotated for quantification and scope along with tense and aspect into *FHTL*. In this work we do not make use of aspect but we discuss a possibility of how to handle it later. Where AMR interpretations given in Lai et al. (2020) and Bos (2016) translate AMR into first-order predicate logic via a direct and stateless transformation on the AMR, we elected to demonstrate a stateful approach using pseudocode, since it is clearer how to extract and interpret tense information this way. The core of our interpretation process is taken from Pustejovsky et al. (2019), since the `scope` node dictates order and application of the interpretation of the subgraphs in the AMR. We assume the AMR’s temporal information is attached to the concept at the `scope`’s `pred` node, and integrate that into the translation to achieve an interpretation in *FHTL* instead of first-order predicate logic.

0.6.1 Examples

Here we consider some AMR examples using both extensions and their corresponding acceptable *FHTL* translations:

- (1) a. Every desk will have a computer located there.

b.

```
(s / scope
  :pred (b / be-located-at-91 :ongoing -
          :complete +
          :time (a / after
                 :op1 (n / now))
  :ARG0 (c / computer)
  :ARG1 (d / desk)
```

```

:quant (e / every)))
:ARG0 d
:ARG1 c)
c. @now( $\forall y$ )[desk( $y$ ) → ( $\exists x$ )[computer( $x$ ) ∧  $F(\text{be-located-at-91}(x,y))$ ]]
d. Also acceptable but with a subtle difference Every desk (in the future) will have a computer located there (future computers and desks):
@now $F((\forall y)[\text{desk}(y) \rightarrow (\exists x)[\text{computer}(x) \wedge \text{be-located-at-91}(x,y)]])$ 

```

(2) a. Carl filled out the forms and everyone will submit them tomorrow.

b.

```

(a / and
:op1 (s / scope
:pred (f / fill-out-03 :ongoing -
:complete +
:time (b / before
:op1 (n / now))

:ARG0 (p / person
:name (n2 / name
:op "Carl"))

:ARG1 (f2 / form))

:ARG0 p
:ARG1 f2)

:op2 (s2 / scope
:pred (m / submit-01 :ongoing -
:complete +
:time (a2 / after
:op1 n / now))

:ARG0 (p2 / person
:mod (a3 / all))

:ARG1 f2)

```

```
:ARG0 f2
:ARG1 p2))
```

c. Technically correct:

$$@now(\exists x)[\text{form}(x) \wedge P(\text{fill-out-03}(\text{Carl}, x))) \wedge @now(\exists x)[\text{form}(x) \wedge (\forall y)[\text{person}(y) \rightarrow F(\text{submit-01}(y, x))]]$$

d. Correct with regard to reentrance:

$$@now(\exists x)[\text{form}(x) \wedge P(\text{fill-out-03}(\text{Carl}, x)) \wedge (\forall y)[\text{person}(y) \rightarrow F(\text{submit-01}(y, x))]]$$

0.6.2 Extraction Steps

With the chosen annotation, the root node can consist of either a logical connective (and, or, or cond) linking two or more AMR graphs, or a scope node with its following predicate and arguments. In the former case we interpret the arguments and join them together via the meaning of the connective, e.g. for:

```
(3) (o / or
      :op1 (...))
      :op2 (...))
      :op3 (...))
```

The meaning in *FHTL* is $[:op1] \vee [:op2] \vee [:op3]$. In the case where the root node of the AMR is scope, the order of interpretation is specified. For instance in example 1, the order of interpretation is $[\![\text{ARG0}]\!](\![\!\text{ARG1}\!]\!(\![\!\text{pred}\!]\!))$. Finally, we have that the meaning of every AMR with a scope root will be prefixed by a satisfaction operator with a nominal indicating the time of reference provided in the :time relation (if that time is “now” then we let the nominal indicate the document creation time where available).

0.6.3 General Extraction Algorithm

In figure 5, InterpretEntry and InterpretClause perform essentially what we discussed in subsection 0.6.2. We should note that in InterpretClause the interpreted predicate takes the tense operator as an argument. We do not provide definitions for Tense and Reference

```

Def InterpretEntry (AMR) :
    root = Root(AMR)
    now = current date/time
    if root ∈ {and, or, cond} then
        connective = filter(root, { $\wedge$ ,  $\vee$ ,  $\rightarrow$ })
        clauses = []
        for op ∈ Children(root) do
            | append(clauses, InterpretClause (op))
        end
        return @now join(connective, clauses)
    end
    return @now InterpretClause (root)

Def InterpretClause (AMR) :
    time = Time (AMR)
    nominal = Reference (time)
    tense = Tense (time)
    pred = Pred (AMR)(tense)
    Arg0, Arg1 = GetArgs (AMR)
    return @nominal Apply (Arg0, Apply (Arg0, pred))

```

Figure 5: Basic transformation into *FHTL* clauses and connectives.

since they are issues of checking nodes in the AMR graph. Similarly, `Pred` and `GetArgs` are issues of straightforward graph traversal and modifications to the standard interpretation processes which we will show later. In our representation the central predicate is in the immediate scope of the tense operator. From example 0.6.2 we can see that there is another choice, namely having the entire sentence (except for the satisfaction operator) within the scope of the tense operator. This subtle difference in meaning is lost in the AMR, so which interpretation is used in implementation is a design choice, perhaps based on further examination of the interaction of quantification in tense in natural language.

In figure 6, `Apply` is the standard continuation based application of predicates (Van Eijck and Unger, 2010). `InterpretConcept` handles AMR concepts possibly with nested `:mod` relations, to other concepts, letting us extract

$$@_t(\forall x)((\text{dog}(x) \wedge \text{friendly}(x)) \rightarrow P(\text{bark}(x)))$$

from *Every friendly dog barked* rather than recursively obtaining a Neo-Davidsonian representation

$$@_t(\forall d)(\text{dog}(d) \wedge (\exists f)(\text{friendly}(f) \wedge \text{mod}(d, f)) \wedge P(\text{bark}(d)))$$

as in Lai et al. (2020). `InterpPropMod` handles AMR concepts which modify entire sentences/propositions such as negation.

0.7 Future Work

0.7.1 \downarrow and Quantification over Nominals

Hansen (2007) includes treatment of two operators which we have omitted, namely \downarrow and E . \downarrow binds a nominal to the point of evaluation. For instance in $@_a \downarrow w. \varphi$, we have that $\downarrow w. \varphi$ is the case at a , if and only if φ is the case at w ($@_w \varphi$) when a refers to w . This feature affords representation of statements such as *Caroline is the current chief architect* via a formula of the form $\downarrow x. (c = @_x a)$

```

Def Apply (pred1,pred2) :
| return  $\lambda \varphi. \varphi(\lambda \psi. \text{pred}_1(\lambda \gamma. \text{pred}_2(\lambda \gamma. \varphi(\gamma(\psi)))))$ 

Def InterpretConcept (Concept) :
/* Propositional modifiers are handled differently than predicates.
 */
if isPropMod(name(Concept)) then
| return InterpPropMod (Concept)
end
if isVerb(name(Concept)) then
| return InterpretPred (Concept)
end
/* Noun possibly with adjectives.
 */
if hasMods(Concept) then
| mods = [name(Concept)]
| for mod  $\in$  Children(Concept) do
| | append(mods, name(mod)(x))
| end
| FinalPred =  $\lambda x. \text{join}(\text{mods}, \wedge)$ 
end
else
| FinalPred =  $\lambda x. \text{name}(\text{Concept})(x)$ 
end
if Quant(Concept) == :all then
| return  $\lambda k. \forall x [\text{FinalPred}(x) \rightarrow k(x)]$ 
end
else
| return  $\lambda k. (\exists x)[\text{FinalPred}(x) \wedge k(x)]$ 
end

Def InterpretPred (Predicate) :
/* In any implementation PropBank would be referenced for the correct
   number of predicates.
 */
return  $\lambda \varphi. \varphi(\lambda x_1 \dots \lambda x_n. \text{Predicate}(x_1 \dots x_n))$ 

Def InterpPropMod (PropMod) :
if PropMod == not then
| return  $\lambda p. \lambda k. \neg p(k)$ 
end

```

Figure 6: Supporting methods.

where c is a rigid designator (for us a constant) denoting *Caroline* and a is a non-rigid designator (for us a unary function symbol) denoting *chief architect* (Blackburn and Marx, 2002). Intuitively E is existential quantification over nominals (and $\neg E \neg \equiv A$ is universal quantification over nominals), i.e. $@_s E\varphi$ if there is some nominal j such that $@_j\varphi$. Quantification over nominals gives us an entry into handling aspect in addition to tense. For instance, the `:stable +` and `:stable -` aspects from Donatelli et al. (2018) can be modeled via A and \downarrow respectively. The different modes of `:ongoing` ostensibly could be modeled with operators from computation tree logic such as `finally` and `until` (May and Schmitt, 1996). `:habitual` is the most problematic case, since this would require generalized quantification over nominals, making inference and model checking very expensive if nothing else.

0.7.2 Implementing Theorem Proving and Model Checking

Now that we have a general approach for automated inference and model checking of first-order hybrid logic, there is the question of implementation. HTab (Hoffmann and Areces, 2009) provides an implementation of $\mathcal{H}(@, A)$, (propositional hybrid logic with quantification over nominals) which does not natively provide a way to reason with P or first-order quantification. While it may be possible to extend HTab to accommodate these, it might be more productive to consider theorem provers for first-order modal logic utilizing tableau such as leanTAP (Beckert and Posegga, 1995) and extending them to accommodate hybrid logic's satisfaction operator and the other aspects of *FHTL*. MDK-verifier¹ is the only modal model checker we are aware of, and currently handles only the propositional modal logic K .

0.7.3 The Future of AMR and Parsing for Semantic Features

AMR parsing is an area which receives a great deal of attention, however we are not aware of many efforts in AMR parsing towards accommodating extensions which enable direct inference. Indeed, whether any research in automated reasoning over AMR and its extensions is of practical

¹<http://www.cril.univ-artois.fr/~montmirail/mdk-verifier/>

relevance depends entirely on whether AMR parsers can accomplish this in a reasonably effective way. Determining where and to what extent AMR parsing for extensions is effective is a worthwhile pursuit for AMR researchers in general, whether or not they are concerned with these extensions' suitability for inference.

0.8 Conclusion

We have demonstrated how the core aspects of AMR along with extensions for scope, quantification, and tense, can be interpreted in first-order hybrid tense logic, and that *FHTL* affords reasoning for these translated AMR sentences, through its general tableau method which acts as a proof procedure for *FHTL* sentences and its terminating tableau method which acts as a model checker. We have discussed the possibility of handling aspect, and some possible strategies for developing an implementation of tableau methods for *FHTL* or another first-order hybrid logic variant. There are questions of both theoretical and pragmatic approaches to optimization of these tableau methods and their implementation, as well as investigating how AMR parsing can become both robust and sensitive enough to realize the goals of this research.
